Magnetic nanoparticle transport within flowing blood and into surrounding tissue

Magnetic drug delivery refers to the physical confinement of therapeutic magnetic nanoparticles to regions of disease, tumors, infections and blood clots. Predicting the effectiveness of magnetic focusing in vivo is critical for the design and use of magnetic drug delivery systems. However, current simple back-of-the-envelope estimates have proven insufficient for this task. In this article, we present an analysis of nanoparticle distribution, in and around a single blood vessel (a Krogh tissue cylinder), located at any depth in the body, with any physiologically relevant blood flow velocity, diffusion and extravasation properties, and with any applied magnetic force on the particles. For any such blood vessel our analysis predicts one of three distinct types of particle behavior (velocity dominated, magnetic dominated or boundary-layer formation), which can be uniquely determined by looking up the values of three nondimensional numbers we define. We compare our predictions to previously published magnetic-focusing in vitro and in vivo studies. Not only do we find agreement between our predictions and prior observations, but we are also able to quantitatively explain behavior that was not understood previously.

**KEYWORDS:** blood vessels - ferromagnetic nanoparticles - in vivo experiments - magnetic drug targeting - nondimensional parameters - simulations - tissue - treatment depth

In magnetic drug targeting, magnetic particles containing or coated with therapeutics are concentrated to sites of disease by applied magnetic fields. This has allowed focusing of chemotherapy to solid tumors in Phase I human clinical trials [1], and in animal experiments [2–5], and is being used to target drugs to other types of disease locations (e.g., to regions of thrombosis [6]). During such treatments, magnetic particles are usually injected into the bloodstream, and magnets are then used to concentrate them to target locations. There is a need to know which locations can or cannot be effectively reached by magnetic drug targeting. Key issues include whether the applied magnetic forces can hold nanoparticles against blood flow, and at which body depth, in which blood vessels, and how far particles subsequently travel from the vessels into surrounding tissue.

Physical parameters, such as particle size and materials, as well as magnet placement, size, shape and strength, are crucial for the success of magnetic drug focusing. However, there is little ability to predict how these parameters will affect particle behavior in vivo. This has forced critical magnetic drug delivery design choices to be made based on intuition, empirical data and simple engineering estimates – and these rough tools are proving insufficient. For example, the question of whether magnets can or cannot hold nanoparticles against blood flow is often addressed when designing experiments by comparing the maximum force that the blood flow exerts on a particle against the applied magnetic force. This analysis underpredicts the ability of a magnetic field to hold particles against blood flow, and does not match behavior observed in animal experiments. In rats, the slowest blood flow velocity, in capillaries, has been measured to be approximately 0.1 mm/s [7], a velocity that will create a (Stokes) drag force [8] of

\[ F_{\text{blood}} \approx 7 \times 10^{-13} \text{ Newtons} \]  

on a 250 nm diameter particle at the vessel center. For the rat experiments shown in Figure 1, a 0.5 Tesla, 5 cm long, 5 mm wide permanent magnet was used to concentrate 250 nm diameter iron oxide nanoparticles underneath the skin against blood flow. The magnetic field created by this magnet, and the resulting magnetic force [8], works out to be only

\[ F_{\text{mag}} \approx 1 \times 10^{-13} \text{ Newtons} \], a factor of a seventh smaller. This calculation suggests that blood flow forces will overcome the applied magnetic forces; yet, magnetic drug focusing was clearly observed, as shown in Figure 1. This experiment was repeated for 100 nm particles, in which case the magnetic force is 109 times smaller than the vessel centerline blood drag force, yet focusing remained successful.

Methods

As shown in Figure 2B, we focus our attention on nanoparticle behavior in and around a single blood vessel (a Krogh tissue cylinder geometry [9]). This blood vessel can be of any type, from a major artery or a vein, to a minor capillary, fenestrated or not, at any depth, and any applied magnetic force can be considered. Instead of using simple engineering estimates, starting from physical first principles, we state and then solve the equations governing the diffusion, convection and magnetic transport of nanoparticles in the blood and into surrounding tissue. These equations describe the time progression of the nanoparticle concentration at every spatial location in the blood and surrounding tissue. The first equation captures particle transport due to convection by blood flow, particle diffusion (including particle scattering by collisions with blood cells [10]), and particle motion due to magnetic forces (see [11] for details).

\[
\frac{\partial C_p}{\partial t} = -\nabla \cdot \left( \frac{1}{Pe} \nabla C_p + \left( 0, -\Psi \right) C_p \right)
\]

(1)

Here, \(C_p\) is the concentration of particles at each location in the blood, \(\bar{v}\) is the blood velocity, \(t\) is time, \(\nabla\) is the gradient operator, and \(Pe\) and \(\Psi\) are the Péclet and magnetic-Richardson numbers. The next two equations include diffusion and transport in the endothelial membrane and surrounding tissue. This type of formulation is standard, and, as in [9], extravasation (or lack thereof) is modeled by adjusting the diffusion coefficient in the endothelium, \(D\), to a nonzero (or zero) value. Additional tissue-specific properties, for example, decreased resistance to nanoparticle motion owing to a compromised extracellular matrix with larger interstitial spaces in a tumor region, can be accounted for by decreasing the magnetic drift coefficient (the magnetic-Richardson number), \(\Psi\), in that region. Increased interstitial tumor pressure can decrease blood flow velocity into a tumor and, therefore, is reflected by choosing an appropriately lower \(\bar{v}_{max}\) velocity in affected blood vessels.

\[
\frac{\partial C_{M}}{\partial t} = -\nabla \cdot \left( -\frac{1}{Pe} \nabla C_{M} + (0, -\Psi) C_{M} \right)
\]

\[
\frac{\partial C_{T}}{\partial t} = -\nabla \cdot \left( -\frac{1}{Pe} \nabla C_{T} + (0, -\Psi) C_{T} \right)
\]

(2)

\(C_{M}\) and \(C_{T}\) are the concentrations of particles at every location in the endothelial membrane and tissue, and \(D\) and \(D_{T}\) are the endothelium and tissue Renkin-reduced diffusion coefficients. As shown in Figure 2B, it is assumed that the blood vessel is aligned perpendicularly to the applied magnetic force. If the vessel is at an angle to the magnetic force, then only the perpendicular part of the force should be used for \(F_{M}\) below, and the tangential part can be added to the drag forces along the blood vessel, to \(F_{T}\). These equations are stated in
nondimensional variables, meaning the variables used have been chosen to highlight the competition between phenomena: between blood drag and magnetic forces, and between diffusion in the blood and surrounding tissue. This nondimensional scaling reveals the key numbers $\Psi$, $D$, $D_T$, and $Pe$, which uniquely determine particle behavior [11].

Specifically, the magnetic–Richardson number, $\Psi$, quantifies the ratio between the applied magnetic forces and the maximum drag forces that the blood in that vessel can exert on the nanoparticles. We define it as the ratio:

$$\Psi = \frac{\text{Magnetic force at vessel centerline}}{\text{Stokes drag force at centerline}} = \frac{||F_M||}{||F_S||} = \frac{\frac{\mu V}{\eta V_{bmax}}}{\frac{\mu V}{\eta V_{bmax}}},$$

The magnetic force depends both on the magnetic field $\mu$ (units: A/m) created by the magnet and its spatial gradient $\frac{dH}{dx}$ (A/m²), and both must be known at the vessel location to compute the magnetic force (see [11] and Supplementary Figure 1 [www.futuremedicine.com/doi/suppl/10.2217/nnm.10.104]). In Equation 3, $V$ is the equilibrium velocity (m/s) of the nanoparticle created by the applied magnetic force. To compute $\Psi$, as well as $D$, $D_T$, and $Pe$, all variables should be stated in SI units (e.g., as $a = 10^{-7}$ m for a 100 nm radius particle, then all units will exactly cancel, yielding the four nondimensional numbers; see the detailed instructions in the supplementary material and in [11]).

As the magnetic–Richardson number increases beyond 1, the magnetic force exceeds the blood drag force at the vessel centerline. Thus, the Richardson number is a key indicator of the success of magnetic drug focusing, but, as noted previously, magnetic focusing can occur even if this number is substantially below 1 (as in the rat example).

The second key number that determines the success of magnetic drug delivery is the mass Péclet number [12]. It quantifies the competition between particle movement (convection) by blood flow versus particle diffusion in the blood, and is defined as:

$$Pe = \frac{\text{Blood vessel width} \times \text{maximum blood velocity}}{\text{Total diffusion coefficient of particles}} = \frac{D_T V_{bmax}}{D_{bmax}}.$$

Here, $D_{bmax}$ (in m²/s) takes into account the scattering of nanoparticles by collisions with blood cells, an effect that can be modeled as additional diffusion [10]. For 250 nm diameter particles in rat capillaries, $Pe \approx 1000$, meaning nanoparticles are convected much faster than they diffuse.

Finally, the Renkin-reduced diffusion coefficients [9], for the endothelium membrane and the surrounding tissue, are defined as:

$$D = \frac{\text{Diffusion coefficient in membrane}}{\text{Total diffusion coefficient in blood}} = \frac{D_M}{D_M + D_b},$$

$$D_T = \frac{\text{Diffusion coefficient in tissue}}{\text{Total diffusion coefficient in blood}} = \frac{D_T}{D_{bmax}}$$

where $D_M$ is the particle diffusion in blood caused by thermal fluctuations, $D_T$ is the additional diffusion caused by collision with blood cells, $D_M$ is the diffusion in the endothelial membrane (it is set to zero if there is no extravasation), and $D_T$ is the particle diffusion in surrounding tissue (all in units m²/s). As an example, for 250 nm diameter particles, leaky tumor rat capillaries with fenestrations on the order of 600 nm have a membrane Renkin coefficient of $D \approx 0.36$; for a tumor extracellular spacing of 1 μm, the tissue Renkin coefficient is $D_T \approx 0.56$ [9].

Under physiological conditions, for vessel diameters and blood velocities ranging from $d_b = 6$ μm and $V_{bmax} = 0.1$ mm/s (rat capillaries) to $d_b = 3$ cm and $V_{bmax} = 40$ cm/s (human aorta), and for achievable physical parameters, particle diameters ranging from 1 nm to 5 μm, and magnet field strengths no greater than 4 Tesla (MRI strengths), the four nondimensional parameters can range between $4 \times 10^{-13} \leq \Psi \leq 6 \times 10^{10}$, $1 \leq Pe \leq 1 \times 10^{12}$, and $0 \leq \min(D, D_T) \leq 1$ (it suffices to consider the minimum of the two Renkin coefficients, as the smaller coefficient determines the behavior). To map nanoparticle behaviors across this entire parameter space, we first divided our nondimensional number space (i.e., Richardson, Péclet and Renkin) into a coarse $7 \times 7 \times 5$ grid, and carried out a simulation of particle behavior at each number triplet (a total of 245 simulations). This revealed the three types of behaviors shown in Figure 3 and discussed next. To identify more precisely the boundaries between these three behavior types, we carried out 475 further simulations on a finer grid, which spanned the transitions from one type of behavior to another.

For each Richardson–Péclet–Renkin triplet, we evaluated the transient and final concentration of nanoparticles, in the blood, endothelial membrane and surrounding tissue, according to Equations 1 & 2. Initially, this was done using the commercial multiphysics package COMSOL [101], a package that has been used fairly commonly in the magnetic drug delivery literature for its ability to couple partial differential equations. In the numerical methods community, it is well known that high Péclet number cases are extremely difficult to solve; COMSOL
failed to solve cases for $Pe$ values greater than 1300. To achieve the solutions for $Pe$ numbers as high as $10^{12}$, we developed and implemented a sophisticated inhouse numerical method. Our resulting vessel–membrane–tissue (VMT) solver for the partial differential equation 1 & 2 is based on a combination of the following four techniques:

- Factorization of the differential operator as a product of 1D differential operators and efficient solution of the corresponding ordinary differential equations at every time step (the ADI method [13]);
- Use of a graded mesh in the vessel domain;
- Use of changes of unknowns that transform the spatial operators in the membrane and tissue domains into operators of Helmholtz type, which enables the use of highly optimized steady-state solvers;
- An on-and-off fluid-freezing methodology designed to effectively resolve the large timescale separation between the dynamics in the blood domain and the much slower diffusion processes in the membrane and tissue.

The details underlying the VMT solver can be found in [11], and a future contribution in [Beni et al., Manuscript in Preparation]. The VMT solver was both more accurate and 500 times faster than COMSOL, and it was able to solve cases that COMSOL could not. Our recent work shows that significant further improvements of the algorithm are feasible [Beni et al., Manuscript in Preparation].

The VMT simulations predicted nanoparticle behavior for any scenario within the considered range of physiological/feasible circumstances. For any blood vessel, at any body depth, with any diameter, and blood flow velocity, for nanoparticles of any size and material properties under any applied magnetic field, there is a corresponding nondimensional number triplet (Richardson–Péclet–Renkin), given by Equations 3–6, which uniquely determines nanoparticle behavior in and around that blood vessel. By looking up the behavior of that triplet on our grid of 720 conducted simulations, we predicted the type of behavior (Figure S 3 & 4), and compared it against available in vitro and in vivo magnetic drug delivery experiments. We found excellent agreement (Figure 5) and were able to explain observed behavior that was not previously understood.

Results & discussion

Magnetic nanoparticles travel through the blood and into the surrounding tissue under three competing effects: under blood convection, diffusion
Magnetic nanoparticle transport in blood & tissue

Preliminary Communication

Nacev, Beni, Bruno & Shapiro

...transport...by blood cells [9,10], and from the pull of the applied magnetic fields. The Richardson, Péclet, and Renkin numbers quantify the competition between these three effects (Equations 3–6).

Our simulations revealed the three types of behavior shown in Figure 3. In the velocity-dominated case, the created magnetic forces are weak compared with the blood flow forces, so they cannot capture the particles and, therefore, the nanoparticles are washed out the back of the blood vessel. In the magnetic-dominated case, the magnetic forces far exceed the ability of the vessel membrane and tissue to resist particle motion, to the point where the particles are pulled by the magnet out of the vessel and, eventually, also out of the region of tissue being considered. This case either requires exceedingly strong magnetic forces, or a blood vessel membrane that does not substantially inhibit particle movement (e.g., a sufficiently ‘leaky’ tumor vessel). In the boundary-layer case, nanoparticles accumulate in a layer at the vessel wall and, if extravasation is possible, are then in the correct location to enter the surrounding tissue. It is this last case that is most interesting and effective for drug delivery, as the applied magnetic field serves to concentrate the therapeutic.

To understand which behaviors occur, and when, we first show a case for a fixed Péclet number of $Pe = 1000$ (Figure 4), as corresponds to our previous rat capillary example. For each (Richardson–Renkin) pair, it shows which behavior is occurring. The behavior switches from velocity-dominated to boundary-layer cases as the Richardson number increases, but, as seen from the plot, and described earlier, this transition can happen well before the magnetic forces attain the value of blood drag forces at the vessel centerline. For $Pe = 1000$, the boundary-layer behavior begins when $\Psi$ exceeds $5 \times 10^{-5}$ (i.e., when the magnetic forces have reached just 0.005% of the centerline drag forces). The transition from the velocity to boundary-layer behavior is gradual, so we show the delineation between them as a ‘fuzzy’ border. This transition is delayed as the Renkin number increases (the...
angled border at the top of the plot) because, if diffusion in the endothelium and tissue is high, any build-up of particles in the tissue can diffuse more easily back out into the vessel, and then be swept away by blood flow. For the rat capillary example, Figure 4 allows us to read how much magnetic force is necessary to achieve magnetic focusing – from the log scale, the magnetic force applied should be greater than 0.005% of the centerline blood drag force.

The work flow for utilizing the predictive capabilities of this method is outlined in Supplementary Figure 1 (www.futuremedicine.com/doi/suppl/10.2217/nnm.10.104). Initially, the researcher should determine the variables involved in the experiment. Then they should calculate the parameters necessary for determining the nondimensional numbers using the equations provided. Finally, knowing the nondimensional numbers associated with the experiment enables the researcher to predict the nanoparticle behavior within the specific experimental set-up.

Figure 5 provides the dependence on all three nondimensional numbers, as well as a comparison against the five available prior in vitro and in vivo experimental studies of magnetic

![Image of the figure](https://www.futuremedicine.com/doi/suppl/10.2217/nnm.10.104)

**Figure 5.** The experimental domains of prior studies plotted on a 3D representation of the nondimensional number space versus our predictions. The shaded regions show the three behavior types: magnetic dominated against the back in blue; velocity dominated at the bottom left (the curved green ramp shape); and boundary layer formation everywhere else (in white). The in vitro experiments are shown as small boxes [14,16]; the in vivo experiments are shown as large colored wireframes (the two boxes and the extruded curved triangle) [1,5,15]. Regions where the experiments leave the boundary layer formation region and enter the velocity dominated region are denoted by translucent shading (seen in the Lübbe, Widder and Bergemann cases, Ganguly and Xu remain wholly in the boundary layer domain). The outlined shapes cover the range of cases expected in the experiments. In all cases, the observed absence or presence of magnetic drug focusing matched our theoretical predictions. All of these experiments were designed to be successful and they all largely lie in the boundary build-up domain, although for Lübbe [1] there are deeper vessels with faster blood flows which fall into the velocity dominated case. Our analysis correctly predicted when those situations occurred. See [11] for a more detailed version of this figure.
Magnetic nanoparticle transport in blood & tissue

Executive summary

- Our objective was to predict which blood vessels, and surrounding tissue, can (or cannot) be reached by magnetic drug targeting.
- Governing equations describing particle transport in vivo under applied magnetic fields were reduced to depend upon a minimal number of nondimensional numbers: the magnetic-Richardson, Pécelt and Renkin numbers.
- Across all physiological conditions, and for achievable engineering conditions, behavior was found to fall into one of three categories: velocity-dominated, magnetic-dominated or boundary-layer behavior (the desired case, corresponding to a focusing of the nanoparticles by magnetic forces).
- The type of behavior was uniquely predicted by our three nondimensional numbers. A complete mapping was provided, which showed which behavior occurred when.
- The predictions made were in excellent agreement with both in vitro and in vivo prior published magnetic focusing studies, indicating that our method provides an effective way to forecast magnetic drug delivery behavior in and around vessels.

Future perspective

Magnetic drug delivery is emerging as a powerful drug-targeting option, with the ability to physically direct therapeutics to sites of disease [1,4,6]. The design of effective magnetic drug delivery systems is an endeavor that must match engineering to physiology and, as such, it requires an ability to understand and predict how engineering choices (e.g., particle size and composition, magnet placement, shape and strength) affect drug distribution in vivo. This cannot be achieved through animal experiments alone – the number of animals that would be required to exhaustively search the design space is staggering – and current simple back-of-the-envelope analyses have proved insufficient. Thus, there is a broad need for the type of modeling conducted by our group. Although physiological behavior is complex, and predicting it is a great challenge, our current analysis is a sensible next step – it uses physical first principles and available physiological information, and is effective. Weak points of the modeling must now be identified, such as our simple treatment of extravasation as diffusion [9], and should be rank ordered (to assess which weaknesses should be addressed first to improve the predictions and enable better design of next-generation magnetic drug delivery systems) and, then, in vitro and animal experiments must be devised to isolate, understand, measure and fix the weaknesses. For example, we are currently creating experiments to precisely measure particle transport through excised tissue and blood vessel walls under carefully applied magnetic forces to quantify diffusion and extravasation. The suite of tools that we will build will teach us a great deal about the behavior of nanoparticles in vivo, and will enable better design and optimization of next-generation magnetic drug delivery systems.

Papers of special note have been highlighted as:

* of interest
** of considerable interest

** Published study of Phase 1 human clinical trials of magnetic drug targeting with an emphasis on toxicity.

** Engineering approach to biological transport systems, with detailed information on incorporating the biology into an engineering framework.

* Overview of the subtle biological impact on parameters involved in magnetic drug targeting *in vivo*.

** States the governing equations, carries out the nondimensionalization, and derives the three key nondimensional parameters (the Richardson, Peclet and Renkin numbers), exhaustively examines further cases (e.g., nonuniform magnetic forces and curved blood vessels), has a comprehensive literature review, and a detailed comparison to prior published experimental studies.

** Website**

101 COMSOL

www.comsol.com
Start by establishing the following variables, which include magnet, particle and in-vivo parameters. The magnetic field experienced at the target location is determined by the magnet strength, the dimensions of the magnet, and the distance from the magnet. The composition of the particles determines the magnetic core radius, hydrodynamic diameter, and magnetic susceptibility. The location of the target region within the body determines the type of tissue, target depth, and the proximity, size and type of blood vessels [10-11].

**Magnet Parameters**
- **Magnet strength** $B$ [Tesla]
- **Magnet dimensions** $L_{ax} \times w_{ax} \times h_{ax}$ [meters]
- **Distance from magnet to target** $d$ [meters]
- **Permeability of free space** $\mu_0 = 4\pi \times 10^{-7}$ N/A²

**Particle Parameters**
- **Magnetic core radius** $a$ [meters]
- **Hydrodynamic diameter** $d_{hydro}$ [meters]
- **Partial material magnetic susceptibility** $\chi$

**In-vivo Parameters**
- **Body temperature** $T$ [Kelvin]
- **Pore sizes for tissue and membrane** $d_{p,\text{mem}}$, $d_{p,\text{tiss}}$ [meters]
- **Max blood speed** $V_{\text{max}}$ [meters/second]
- **Blood vessel diameter** $d_b$ [meters]
- **Blood viscosity** $\eta$ [Pascal seconds]

Using the parameters established in Step 1, the following equations can calculate the forces and diffusion coefficients necessary to predict the ferrofluid behavior. The magnetic field and gradient are to be evaluated at the target position $(x^*, y^*, z^*)$ from a simulated or measured magnetic vector field. Then calculate the magnetic force. Determine the Stokes drag force by the blood flow speed at the target location. The diffusion coefficients are calculated for the corresponding target region in the biological system.

**Magnet Field**
Use modeling software to compute the magnetic field and its derivative.

$$ \vec{H}(x, y, z) = [H_x, H_y, H_z] $$

**Magnetic Force**
Compute the magnetic force using equation (4) from [12]

$$ F_a = \frac{4}{3} \frac{\pi d^3}{\mu_0} \chi \left( \frac{\partial H^2}{\partial x} \right) $$

**Stokes Drag Force**
Given the blood flow speed at the target location, compute the Stokes drag:

$$ \vec{F}_s = 3 \pi d_{\text{hydro}} \eta V_{\text{max}} $$

**Scattering Coefficient**
Calculate scattering coefficient ($D_a$) in SI units [m²/s] using [10].

**Total diffusion coefficient**
$$ D_{tot} = D_a + D_t $$

**Diffusion Coefficients**
Calculate membrane and tissue diffusion coefficients using [10,11].

From the variables calculated in Step 2, determine the following four non-dimensional numbers. Using these four non-dimensional numbers, the coordinate location within the non-dimensional space can be determined. This location will reveal the ferrofluid behavior.

**Magnetic Richardson Number**
$$ \Psi = \frac{F_a}{F_s} $$

**Mass Peclet Number**
$$ Pe = \frac{d_{p,\text{mem}} V_{\text{max}}}{D_{tot}} $$

**Renkin Diffusion Coefficient**
$$ \Phi = \frac{D_{tot}}{D_{tot}} $$

**Tissue Renkin Diffusion Coefficient**
$$ \Phi_t = \frac{D_{tot}}{D_{tot}} $$

By COMSOL²,

$$ F_a = \frac{4}{3} \pi d_{\text{hydro}} \eta V_{\text{max}} $$

The Stokes drag force is for a capillary near tumors. As noted in [11], the scattering coefficient is not applicable.

$$ \Phi_t = 3 \pi d_{\text{hydro}} \eta V_{\text{max}} $$

The diffusion coefficients are associated with leaky capillaries near tumors. As noted in [11], the scattering coefficient is not applicable.

$$ \Phi_t = 3 \pi d_{\text{hydro}} \eta V_{\text{max}} $$

The four non-dimensional numbers are

$$ \Psi = (1/7) \times 10^{-11} = 0.14 $$
$$ Pe = (0.001 m)(0.0001 m/s)/1 \times 10^9 $$
$$ \Phi = 2.16 \times 10^{-13}/6 \times 10^{-13} = 0.36 $$
$$ \Phi_t = 2.16 \times 10^{-13}/6 \times 10^{-13} = 0.36 $$

**Rat Example**
Below are the parameters for the rat example in Figure 2. The membrane pore diameters correspond to leaky tumor vessels.

$$ B = 0.5 \text{ T } $$
$$ L_{ax} \times w_{ax} \times h_{ax} = (0.05 \times 0.05 \times 0.01) \text{ m } $$
$$ d = 0.001 \text{ m } $$
$$ a = 125 \times 10^{-9} \text{ m } $$
$$ d_{\text{hydro}} = 250 \times 10^{-9} \text{ m } $$
$$ \chi = 20 $$
$$ T = 310 \text{ K } $$
$$ d_{p,\text{mem}} = 600 \times 10^{-9} \text{ m } $$
$$ d_{p,\text{tiss}} = 600 \times 10^{-9} \text{ m } $$
$$ V_{\text{max}} = 0.0001 \text{ m/s } $$
$$ d_b = 6 \times 10^{-4} \text{ m } $$
$$ \eta = 0.003 \text{ Pa \cdot s } $$
